Dynamics of Simple Oscillators
(single degree of freedom systems)

CEE 541. Structural Dynamics
Department of Civil and Environmental Engineering
Duke University
Henri P. Gavin
Fall, 2020

This document describes free and forced dynamic responses of simple oscillators (sometimes called single degree of freedom (SDOF) systems). The prototype single degree of freedom system is a spring-mass-damper system in which the spring has no damping or mass, the mass has no stiffness or damping, the damper has no stiffness or mass. Furthermore, the mass is allowed to move in only one direction. The horizontal vibrations of a single-story building can be conveniently modeled as a single degree of freedom system. Part 1 of this document describes some useful trigonometric identities. Part 2 shows how damped oscillators vibrate freely after being released from an initial displacement and velocity. Part 3 covers the response of damped oscillators to persistent sinusoidal forcing.

Consider the structural system shown in Figure 1,

![Figure 1. The proto-typical oscillator.](image-url)
where:

\[ f(t) \] = external excitation force

\[ x(t) \] = displacement of the center of mass of the moving object

\[ m \] = mass of the moving object

\[ f_I = \frac{d}{dt}(m\ddot{x}(t)) = m\dddot{x}(t) \]

\[ c \] = linear viscous damping coefficient

\[ f_D = c\dot{x}(t) \]

\[ k \] = linear elastic stiffness coefficient

\[ f_S = kx(t) \]

In structures made of components that bend (i.e., beams), the stiffness coefficients, \( k \), relating collocated forces and displacements depend on the configuration of the beam and the loading, as shown in Figure 2.

![Figure 2. Stiffness coefficients](image)

The damping coefficient, \( c \), relates point forces and collocated velocities. The damping model \( f_D = c\dot{x}(t) \) is a linear viscous approximation for the truly complicated energy dissipating mechanisms within and around structures, including friction, visco-elasticity, inelastic deformation, and air resistance. In oscillating structures, damping forces are generally much smaller than inertial and elastic forces. A linear viscous damping approximation is sufficiently accurate in such cases.
The mass coefficient, $m$, represents the combination rigid massive components and some portion of the mass of interconnected flexible components.

In a simple oscillator as shown in Figure 1, the kinetic energy $T(x, \dot{x})$, the potential energy, $V(x)$, and the external forcing and dissipative forces, $p(x, \dot{x})$, are

\[
T(x, \dot{x}) = \frac{1}{2}m(\dot{x}(t))^2 \\
V(x) = \frac{1}{2}k(x(t))^2 \\
p(x, \dot{x}) = -c\dot{x}(t) + f(t)
\]

The general form of the differential equation describing a simple oscillator follows directly from Lagrange’s equation,

\[
\frac{d}{dt} \frac{\partial T(x, \dot{x})}{\partial \dot{x}} - \frac{\partial T(x, \dot{x})}{\partial x} + \frac{\partial V(x)}{\partial x} - p(x, \dot{x}) = 0 ,
\]

or from simply balancing the forces on the mass,

\[
\sum F = 0 : f_I + f_D + f_S = f(t) .
\]

Either way, the differential equation of motion is:

\[
m\ddot{x}(t) + c\dot{x}(t) + kx(t) = f(t), \quad x(0) = d_o, \quad \dot{x}(0) = v_o
\]

where the initial displacement is $d_o$, and the initial velocity is $v_o$.

The solution to equation (6) is the sum of a homogeneous part (free response) and a particular part (forced response). This document describes free responses of all types and forced responses to simple-harmonic forcing.
1 Trigonometric and Complex Exponential Expressions for Oscillations

1.1 Constant Amplitude

An oscillation, $x(t)$, with amplitude $\bar{X}$ and frequency $\omega$ can be described by sinusoidal functions. These sinusoidal functions may be equivalently written in terms of complex exponentials $e^{\pm i\omega t}$ with complex coefficients, $X = A + iB$ and $X^* = A - iB$. (The complex constant $X^*$ is called the complex conjugate of $X$.)

$$\begin{align*}
x(t) &= \bar{X} \cos(\omega t + \theta) \\
&= a \cos(\omega t) + b \sin(\omega t) \\
&= X e^{+i\omega t} + X^* e^{-i\omega t}
\end{align*}$$ (7)

To relate equations (7) and (8), recall the cosine of a sum of angles,

$$\bar{X} \cos(\omega t + \theta) = \bar{X} \cos(\theta) \cos(\omega t) - \bar{X} \sin(\theta) \sin(\omega t)$$ (10)

Comparing equations (10) and (8), we see that

$$a = \bar{X} \cos(\theta), \quad b = -\bar{X} \sin(\theta), \quad \text{and} \quad a^2 + b^2 = \bar{X}^2$$ (11)

Also, the ratio $b/a$ provides an equation for the phase shift, $\theta$,

$$\tan(\theta) = -\frac{b}{a}$$ (12)

To relate equations (8) and (9), recall the expression for a complex exponent in terms of sines and cosines,

$$\begin{align*}
X e^{+i\omega t} + X^* e^{-i\omega t} &= (A + iB) (\cos(\omega t) + i \sin(\omega t)) + \\
&\quad (A - iB) (\cos(\omega t) - i \sin(\omega t)) \\
&= A \cos(\omega t) - B \sin(\omega t) + i A \sin(\omega t) + i B \cos(\omega t) + \\
&\quad A \cos(\omega t) - B \sin(\omega t) - i A \sin(\omega t) - i B \cos(\omega t) \\
&= 2A \cos(\omega t) - 2B \sin(\omega t)
\end{align*}$$ (13)

Comparing equations (14) and (8), we see that

$$a = 2A, \quad b = -2B, \quad \text{and} \quad \tan(\theta) = \frac{B}{A}.$$ (15)
Any sinusoidal oscillation $x(t)$ can be expressed equivalently in terms of equations (7), (8), or (9); the choice depends on the application, and the problem to be solved. Equations (7) and (8) are easier to interpret as describing a sinusoidal oscillation, but equation (9) can be much easier to work with mathematically. These notes make use of all three forms.

One way to interpret the complex exponential notation is as the sum of complex conjugates,

$$X e^{+i\omega t} = [A \cos(\omega t) - B \sin(\omega t)] + i[A \sin(\omega t) + B \cos(\omega t)]$$

and

$$X^* e^{-i\omega t} = [A \cos(\omega t) - B \sin(\omega t)] - i[A \sin(\omega t) + B \cos(\omega t)]$$

as shown in Figure 4. The sum of complex conjugate pairs is real, since the imaginary parts cancel out. The amplitude, $\bar{X}$, of the oscillation $x(t)$ can be found by finding the the sum of the complex amplitudes $|X|$ and $|X^*|$. 

$$\bar{X} = |X| + |X^*| = 2\sqrt{A^2 + B^2} = \sqrt{a^2 + b^2} \quad (16)$$

Note, again, that equations (7), (8), and (9) are all equivalent using the relations among $(a,b)$, $(A,B)$, $\bar{X}$, and $\theta$ given in equations (11), (12), (15), and (16).
1.2 Decaying Oscillations

The dynamic response of damped systems decays over time. Note that damping may be introduced into a structural system through diverse mechanisms, including linear viscous damping, nonlinear viscous damping, viscoelastic damping, friction damping, and plastic deformation. Ill but linear viscous damping are somewhat complicated to analyze, so we will restrict our attention to linear viscous damping, in which the damping force $f_D$ is proportional to the velocity, $f_D = c \ddot{x}$.

To describe an oscillation which decays with time, we can multiply the expression for a constant amplitude oscillation by a positive-valued function which decays with time. Here we will use a real exponential, $e^{\sigma t}$, where $\sigma < 0$. 

Figure 4. Complex conjugate oscillations.
Multiplying equations (7) through (9) by $e^{\sigma t}$,

$$x(t) = e^{\sigma t} \bar{X} \cos(\omega t + \theta)$$

$$= e^{\sigma t} (a \cos(\omega t) + b \sin(\omega t))$$

$$= e^{\sigma t} (X e^{i\omega t} + X^* e^{-i\omega t})$$

$$= X e^{(\sigma + i\omega) t} + X^* e^{(\sigma - i\omega) t}$$

$$= X e^{\lambda t} + X^* e^{\lambda^* t}$$

Again, note that all of the above equations are exactly equivalent. The exponent $\lambda$ is complex, $\lambda = \sigma + i\omega$ and $\lambda^* = \sigma - i\omega$. If $\sigma$ is negative, then these equations describe an oscillation with exponentially decreasing amplitudes. Note that in equation (18) the unknown constants are $\sigma$, $\omega$, $a$, and $b$. Angular frequencies, $\omega$, have units of radians per second. Circular frequencies, $f = \omega/(2\pi)$ have units of cycles per second, or Hertz. Periods, $T = 2\pi/\omega$, have units of seconds.

In the next section we will find that for an un-forced vibration, $\sigma$ and $\omega$ are determined from the mass, damping, and stiffness of the system. We will see that the constant $a$ equals the initial displacement $d_o$, but that the constant $b$ depends on the initial displacement and velocity, as well mass, damping, and stiffness.
2 Free response of simple oscillators

Using equation (21) to describe the free response of a simple oscillator, we will set \( f(t) = 0 \) and will substitute \( x(t) = X e^{\lambda t} \) into equation (6).

\[
m \ddot{x}(t) + c \dot{x}(t) + k x(t) = 0 , \quad x(0) = d_0 , \quad \dot{x}(0) = v_o , \quad (22)
\]
\[
m \lambda^2 X e^{\lambda t} + c \lambda X e^{\lambda t} + k X e^{\lambda t} = 0 , \quad (23)
\]
\[
(m \lambda^2 + c \lambda + k)X e^{\lambda t} = 0 , \quad (24)
\]

Note that \( m, c, k, \lambda \) and \( X \) do not depend on time. For equation (24) to be true for all time,

\[
(m \lambda^2 + c \lambda + k)X = 0 . \quad (25)
\]

Equation (25) is trivially satisfied if \( X = 0 \). The non-trivial solution is \( m \lambda^2 + c \lambda + k = 0 \). This is quadratic equation is called the characteristic equation of the differential equation (6) and has conjugate roots,

\[
\lambda_{1,2} = -\frac{c}{2m} \pm \sqrt{\left(\frac{c}{2m}\right)^2 - \frac{k}{m}} . \quad (26)
\]

The solution to a homogeneous second order ordinary differential equation requires two independent initial conditions: an initial displacement and an initial velocity. These two independent initial conditions are used to determine the coefficients, \( X \) and \( X^* \) (or \( A \) and \( B \), or \( a \) and \( b \)) of the two linearly independent solutions corresponding to \( \lambda_1 \) and \( \lambda_2 \).

The level of damping, \( c \), qualitatively affects the conjugate roots, \( \lambda_{1,2} \), and the free response solutions.

- **undamped ... \( c = 0 \)**

If the system has no damping \( (c = 0) \) the conjugate roots, \( \lambda_1 \) and \( \lambda_2 \), are purely imaginary,

\[
\lambda_{1,2} = \pm i \sqrt{k/m} = \pm i \omega_n , \quad (27)
\]

where \( \omega_n \) is called the natural frequency of the system. Undamped systems oscillate freely at their natural frequency, \( \omega_n \). The solution in this case is

\[
x(t) = X e^{i \omega_n t} + X^* e^{-i \omega_n t} = a \cos \omega_n t + b \sin \omega_n t , \quad (28)
\]
which is a *real-valued* function. The real coefficients $a$ and $b$ depend on the initial displacement, $d_o$, and the initial velocity, $v_o$.

- **critically damped** ... $c = c_c$

If $(c/(2m))^2 = k/m$, or, equivalently, if $c = 2\sqrt{mk}$, then the discriminant of the quadratic formula (26) is zero. This special value of damping is called the *critical damping* rate, $c_c$,

$$c_c = 2\sqrt{mk} .$$  \hspace{1cm} (29)

The ratio of the actual damping rate to the critical damping rate is called the *damping ratio*, $\zeta$.

$$\zeta = \frac{c}{c_c} .$$  \hspace{1cm} (30)

The conjugate roots of the characteristic equation (25) are real and are repeated at

$$\lambda_1 = \lambda_2 = -c/(2m) = -c_c/(2m) = -2\sqrt{mk}/(2m) = -\omega_n ,$$  \hspace{1cm} (31)

and note also that

$$\frac{c}{m} = \frac{c_c}{m c_c} = \zeta \frac{2\sqrt{mk}}{\sqrt{m} \sqrt{m}} = 2\zeta \sqrt{\frac{k}{m}} = 2\zeta \omega_n$$  \hspace{1cm} (32)

Using relations $k/m = \omega_n^2$ and $c/m = 2\zeta \omega_n$ the conjugate roots (26) are

$$\lambda_{1,2} = -\zeta \omega_n \pm \omega_n \sqrt{\zeta^2 - 1} .$$

If $\zeta = 1$ the two basic solutions are equal to one another, $e^{\lambda_1 t} = e^{\lambda_2 t} = e^{-\omega_n t}$. In order to admit solutions for arbitrary initial displacements and velocities, the solution must be a combination of two linearly independent functions. In this case,

$$x(t) = a \ e^{-\omega_n t} + b \ t \ e^{-\omega_n t} .$$  \hspace{1cm} (33)

where the real coefficients $a$ and $b$ are determined from the initial displacement, $d_o$, and the initial velocity, $v_o$. Details regarding this unique case are in the next section.
• **under-damped** ... $0 < c < c_c$ ... $0 < \zeta < 1$

If the damping coefficient is positive and less than the critical damping rate, the free response of the system is a decaying oscillation starting from a specified initial displacement and velocity. If $0 < \zeta < 1$, the conjugate roots

$$
\lambda_{1,2} = -\zeta \omega_n \pm \omega_n \sqrt{\zeta^2 - 1} = -\zeta \omega_n \pm i \omega_d
$$

are complex-valued, and where $\omega_d$ is called the *damped natural frequency*. The free response solution is

$$
x(t) = X e^{\lambda_1 t} + X^* e^{\lambda_1^* t} = e^{-\zeta \omega_n t} (a \cos \omega_d t + b \sin \omega_d t),
$$

where the real coefficients $a$ and $b$ depends on the initial displacement, $d_o$, and the initial velocity, $v_o$.

• **over-damped** ... $c > c_c$ ... $\zeta > 1$

If the damping is greater than the critical damping, then the conjugate roots

$$
\lambda_{1,2} = -\zeta \omega_n \pm \omega_n \sqrt{\zeta^2 - 1} = -\zeta \omega_n \pm \omega_d
$$

are real and distinct. If the system is over-damped it will not oscillate freely. The solution is

$$
x(t) = \bar{a} e^{\lambda_1 t} + \bar{b} e^{\lambda_2 t},
$$

which can also be expressed using hyperbolic sine and hyperbolic cosine functions. Using identities for exponentials in terms of cosh and sinh,

$$
x(t) = e^{-\zeta \omega_n t} (\bar{a} e^{+\omega_d t} + \bar{b} e^{-\omega_d t})
$$

$$
x(t) = e^{-\zeta \omega_n t} (\bar{a} (\cosh \omega_d t + \sinh \omega_d t) + \bar{b} (\cosh \omega_d t - \sinh \omega_d t))
$$

$$
x(t) = e^{-\zeta \omega_n t} (a \cosh \omega_d t + b \sinh \omega_d t)
$$

The real coefficients $a = \bar{a} + \bar{b}$ and $b = \bar{a} - \bar{b}$ are determined from the initial displacement, $d_o$, and the initial velocity, $v_o$. 
Some useful facts about conjugate roots are:

- \(-2\zeta\omega_n = \lambda_1 + \lambda_2\)
- \(2\omega_n\sqrt{\zeta^2 - 1} = \lambda_1 - \lambda_2\)
- \(\omega_n^2 = \frac{1}{4}(\lambda_1 + \lambda_2)^2 - \frac{1}{4}(\lambda_1 - \lambda_2)^2\)
- \(\omega_n = \sqrt{\lambda_1\lambda_2}\)
- \(\zeta = -(\lambda_1 + \lambda_2)/(2\omega_n)\)

For any level of damping, the equation of motion (6) can be expressed in terms of mass, natural frequency, and damping ratio instead of mass, stiffness, and damping.

\[
\ddot{x}(t) + 2\zeta\omega_n\dot{x}(t) + \omega_n^2x(t) = \frac{1}{m}f(t), \quad x(0) = d_o, \quad \dot{x}(0) = v_o
\]

2.1 Free response of critically-damped systems

The solution to a homogeneous second order ordinary differential equation requires two independent initial conditions: an initial displacement and an initial velocity. These two initial conditions are used to determine the coefficients of the two linearly independent solutions corresponding to \(\lambda_1\) and \(\lambda_2\). If \(\lambda_1 = \lambda_2\), then the solutions \(e^{\lambda_1 t}\) and \(e^{\lambda_2 t}\) are not independent. In fact, they are identical. In such a case, a new trial solution can be determined as follows. Assume the second solution has the form

\[
x(t) = u(t)be^{\lambda_2 t}, \\
\dot{x}(t) = \dot{u}(t)be^{\lambda_2 t} + u(t)\lambda_2 be^{\lambda_2 t}, \\
\ddot{x}(t) = \ddot{u}(t)be^{\lambda_2 t} + 2\dot{u}(t)\lambda_2 be^{\lambda_2 t} + u(t)\lambda_2^2 be^{\lambda_2 t}
\]

substitute these expressions into

\[
\ddot{x}(t) + 2\zeta\omega_n\dot{x}(t) + \omega_n^2x(t) = 0,
\]
collect terms, and divide by \(be^{\lambda_2 t}\), to get
\[
\ddot{u}(t) + 2\omega_n(\zeta - 1)\dot{u}(t) + 2\omega_n^2(1 - \zeta)u(t) = 0
\]
or \(\ddot{u}(t) = 0\) (since \(\zeta = 1\)). If the acceleration of \(u(t)\) is zero then the velocity of \(u(t)\) must be constant, \(\dot{u}(t) = C\), and \(u(t) = Ct\), from which the new trial solution is found.
\[
x(t) = u(t)be^{\lambda_2 t} = b \cdot t \cdot e^{\lambda_2 t}.
\]
So, using the complete trial solution \(x(t) = ae^{\lambda t} + bte^{\lambda_2 t}\), and incorporating initial conditions \(x(0) = d_o\) and \(\dot{x}(0) = v_o\), the free response of a critically-damped system is:
\[
x(t) = d_o \cdot e^{-\omega_n t} + (v_o + \omega_n d_o) \cdot t \cdot e^{-\omega_n t}. \tag{44}
\]

2.2 Free response of under-damped systems

If the system is under-damped then \(0 < \zeta < 1\) and the conjugate roots \((34)\) of the characteristic equation \((25)\) are complex-valued. Solving for the coefficients \(a\) and \(b\) (or \(X\)) of the under-damped free response equation \((35)\) in terms of the initial position, \(x(0) = d_o\) and the initial velocity of the mass is \(\dot{x}(0) = v_o\),
\[
x(0) = d_o = Xe^{\lambda^0} + X^*e^{\lambda^*0} \tag{45}
\]
\[
= X + X^* \tag{46}
\]
\[
= (A + iB) + (A - iB) = 2A = a. \tag{47}
\]
\[
\dot{x}(0) = v_o = \lambda Xe^{\lambda^0} + \lambda^* X^*e^{\lambda^*0}, \tag{48}
\]
\[
= \lambda X + \lambda^* X^*, \tag{49}
\]
\[
= (\sigma + i\omega_d)(A + iB) + (\sigma - i\omega_d)(A - iB), \tag{50}
\]
\[
= \sigma A + i\omega_d A + i\sigma B - \omega_d B +
\]
\[
\sigma A - i\omega_d A - i\sigma B - \omega_d B, \tag{51}
\]
\[
= 2\sigma A - 2\omega B \tag{52}
\]
\[
= -\zeta\omega_n \cdot d_o - 2\omega_d B, \tag{53}
\]
from which we can solve for \(B\) and \(b\),
\[
B = -\frac{v_o + \zeta\omega_n d_o}{2\omega_d} \quad \text{and} \quad b = \frac{v_o + \zeta\omega_n d_o}{\omega_d}. \tag{54}
\]
Putting this all together, the free response of an under-damped system to an arbitrary initial condition, \(x(0) = d_0, \dot{x}(0) = v_0\) is

\[x(t) = e^{-\zeta \omega_n t} \left( d_0 \cos \omega_d t + \frac{v_0 + \zeta \omega_n d_0}{\omega_d} \sin \omega_d t \right). \tag{55}\]
2.3 Free response of over-damped systems

If the system is over-damped, then $\zeta > 1$, $\sqrt{\zeta^2 - 1}$ is real, and the conjugate roots (36) of the characteristic equation (25) are real, distinct, and negative. Substituting arbitrary and independent initial conditions $x(0) = d_o$ and $\dot{x}(0) = v_o$ into the general expression for the over-damped free response (40) results in

$$x(t) = e^{-\zeta \omega_n t} \left( d_o \cosh \omega_d t + \frac{v_o + \zeta \omega_n d_o}{\omega_d} \sinh \omega_d t \right).$$

(56)

Figure 7. Free response of critically-damped (yellow) and over-damped (violet) oscillators to an initial displacement and velocity.

The undamped free response can be found as a special case of the under-damped free response. While special solutions exist for the critically damped response, this response can also be found as limiting cases of the under-damped or over-damped responses.
2.4 Finding the natural frequency from self-weight displacement

Consider a spring-mass system in which the mass is loaded by gravity, \( g \). The static displacement \( D_{st} \) is related to the natural frequency by the constant of gravitational acceleration.

\[
D_{st} = mg/k = g/\omega_n^2 \tag{57}
\]

2.5 Finding the damping ratio from free response

Consider the value of two peaks of the free response of an under-damped system, separated by \( n \) cycles of motion

\[
x_1 = x(t_1) = e^{-\zeta\omega_n t_1}(A) \tag{58}
\]
\[
x_{1+n} = x(t_{1+n}) = e^{-\zeta\omega_n(t_1+2n\pi/\omega_d)}(A) \tag{59}
\]

The ratio of these amplitudes is

\[
\frac{x_1}{x_{1+n}} = \frac{e^{-\zeta\omega_n t_1}}{e^{-\zeta\omega_n(t_1+2n\pi/\omega_d)}} = \frac{e^{-\zeta\omega_n t_1}}{e^{-\zeta\omega_n t_1}e^{-2n\pi\zeta/\omega_d}} = e^{2n\pi\zeta/\sqrt{1-\zeta^2}}, \tag{60}
\]

which is independent of \( \omega_n \) and \( \omega_d \). Defining the log decrement, \( \delta(\zeta) \)

\[
\delta(\zeta) = \frac{1}{n} \ln \left( \frac{x_1}{x_{1+n}} \right) = \frac{2\pi\zeta}{\sqrt{1-\zeta^2}} \tag{61}
\]

and, inversely,

\[
\zeta(\delta) = \frac{\delta}{\sqrt{4\pi^2 + \delta^2}} \approx \frac{\delta}{2\pi} \tag{62}
\]

where the approximation is accurate to within 3% for \( \zeta < 0.2 \) and is accurate to within 1.5% for \( \zeta < 0.1 \).
2.6 Summary of free response of undamped and under-damped oscillators

To review, some of the important expressions relating to the free response of a simple oscillator describe:

- steady oscillatory motion, in three equivalent ways
  \[ x(t) = \bar{X} \cos(\omega t + \theta) = a \cos(\omega t) + b \sin(\omega t) = X e^{i \omega t} + X^* e^{-i \omega t} \]
  \[ \bar{X} = \sqrt{a^2 + b^2}; \quad \tan(\theta) = -b/a; \quad X = A + iB; \quad A = a/2; \quad B = -b/2; \]

- differential equations of motion, in two equivalent ways
  \[
  \begin{aligned}
  m \ddot{x}(t) + c \dot{x}(t) + kx(t) &= 0 \\
  \ddot{x}(t) + 2 \zeta \omega_n \dot{x}(t) + \omega_n^2 x(t) &= 0
  \end{aligned}
  \]
  \[ x(0) = d_o, \quad \dot{x}(0) = v_o \]

- natural frequency, damping ratio, and damped natural frequency
  \[ \omega_n = \sqrt{\frac{k}{m}} \quad \zeta = \frac{c}{c_c} = \frac{c}{2\sqrt{mk}} \quad \omega_d = \omega_n \sqrt{\zeta^2 - 1} \]

- free response of an undamped or under-damped oscillator
  \[ x(t) = e^{-\zeta \omega_n t} \left( d_o \cos \omega_d t + \frac{v_o + \zeta \omega_n d_o}{\omega_d} \sin \omega_d t \right) \quad (0 \leq \zeta < 1) \]

- how to get the damping ratio from a free response
  \[ \delta = \frac{1}{n} \ln \left( \frac{x_1}{x_1+n} \right) \]
  \[ \zeta(\delta) = \frac{\delta}{\sqrt{4\pi^2 + \delta^2}} \approx \frac{\delta}{2\pi} \]
3 Steady state response of harmonically forced simple oscillators

When subject to simple harmonic forcing with a forcing frequency $\omega$, dynamic systems initially respond with a combination of a transient response at a frequency $\omega_d$ and a steady-state response at a frequency $\omega$. The transient response at frequency $\omega_d$ decays with time, leaving the steady state response at a frequency equal to the forcing frequency, $\omega$. This section examines three ways of applying forcing: forcing applied directly to the mass, inertial forcing applied through motion of the base, and forcing from a rotating eccentric mass.

3.1 Direct Forcing

If the oscillator is dynamically forced with a sinusoidal forcing function, then $f(t) = \bar{F}\cos(\omega t)$, where $\omega$ is the frequency of the forcing, in radians per second. If $f(t)$ is persistent, then after several cycles the system will respond only at the frequency of the external forcing, $\omega$. Let’s suppose that this steady-state response is described by the function

$$x(t) = a \cos \omega t + b \sin \omega t, \quad (63)$$

then

$$\dot{x}(t) = \omega(-a \sin \omega t + b \cos \omega t), \quad (64)$$

and

$$\ddot{x}(t) = \omega^2(-a \cos \omega t - b \sin \omega t). \quad (65)$$

Substituting this trial solution into equation (6), we obtain

$$m\omega^2 \ (\ -a \cos \omega t - b \sin \omega t) +$$
$$c\omega \ (\ -a \sin \omega t + b \cos \omega t) +$$
$$k \ (\ a \cos \omega t + b \sin \omega t) = \bar{F}\cos \omega t. \quad (66)$$

Equating the sine terms and the cosine terms

$$(-m\omega^2a + c\omega b + ka) \cos \omega t = \bar{F} \cos \omega t \quad (67)$$

$$(-m\omega^2b - c\omega a + kb) \sin \omega t = 0, \quad (68)$$
which is a set of two equations for the two unknown constants, $a$ and $b$,
\[
\begin{bmatrix}
k - m\omega^2 & c\omega \\
c\omega & k - m\omega^2
\end{bmatrix}
\begin{bmatrix}
a \\
b
\end{bmatrix}
= 
\begin{bmatrix}
\bar{F} \\
0
\end{bmatrix},
\] (69)
for which the solution is
\[
a(\omega) = \frac{k - m\omega^2}{(k - m\omega^2)^2 + (c\omega)^2} \bar{F},
\] (70)
\[
b(\omega) = \frac{c\omega}{(k - m\omega^2)^2 + (c\omega)^2} \bar{F}.
\] (71)

Referring to equations (7) and (12) in section 1.1, the forced vibration solution (equation (63)) may be written equivalently in three ways
\[
x(t) = a(\omega) \cos \omega t + b(\omega) \sin \omega t
= \bar{X}(\omega) \cos (\omega t + \theta(\omega))
= \bar{X}(\omega) \cos (\omega(t + \tau(\omega))).
\] (72) (73) (74)

The ratio of the response amplitude $\bar{X}(\omega)$ to the forcing amplitude $\bar{F}$ is
\[
\frac{\bar{X}(\omega)}{\bar{F}} = \sqrt{\frac{a^2(\omega) + b^2(\omega)}{\bar{F}^2}} = \frac{1}{\sqrt{(k - m\omega^2) + (c\omega)^2}}.
\] (75)

This equation shows how the response amplitude $\bar{X}$ depends on the amplitude of the forcing $\bar{F}$ and the frequency of the forcing $\omega$, and has units of flexibility.

The angle $\theta$ is the phase between the force $f(t)$ and the response $x(t)$, and
\[
\tan(\theta(\omega)) = -\frac{b(\omega)}{a(\omega)} = -\frac{c\omega}{k - m\omega^2}.
\] (76)

Note that $-\pi < \theta(\omega) < 0$ for all positive values of $\omega$, meaning that in a causal system the displacement response, $x(t)$, lags the external forcing, $f(t)$, and that in a simple oscillator that lag is no more than $\pi$ radians. The time-lag of $x(t)$ is $\tau = \theta(\omega)/\omega$. Note that if the phase lag $\theta(\omega)$ is linear in $\omega$ then the time lag $\tau$ is constant. Such systems are called linear phase systems.
Now let’s re-derive expressions for the dynamic amplitude $\bar{X}(\omega)$ and the phase $\theta(\omega)$ using complex exponential notation!

The differential equations of motion are

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = \bar{F} \cos \omega t = F(\omega)e^{i\omega t} + F^*(\omega)e^{-i\omega t}.$$  \hfill (77)

In a solution of the form, $x(t) = X(\omega)e^{i\omega t} + X^*(\omega)e^{-i\omega t}$, the coefficient $X(\omega)$ corresponds to the exponents with a positive imaginary part ($+i\omega$) and $X^*(\omega)$ corresponds to exponents with a negative imaginary part ($-i\omega$). The exponents are complex conjugates. Positive exponent coefficients and negative exponent coefficients are independent and may be found separately. Further, the negative exponent part is simply the complex conjugate of the positive exponent part. So, considering only the positive exponent solution, the forcing is expressed as $F(\omega)e^{i\omega t}$ and the partial solution $X(\omega)e^{i\omega t}$ is substituted into the forced equations of motion, resulting in

$$(-m\omega^2 + ci\omega + k) X(\omega) e^{i\omega t} = F(\omega) e^{i\omega t},$$ \hfill (78)

from which

$$\frac{X(\omega)}{F(\omega)} = \frac{1}{(k - m\omega^2) + i(c\omega)}, \hfill (79)$$

which is complex-valued. This complex function has a magnitude

$$\left|\frac{X(\omega)}{F(\omega)}\right| = \frac{1}{\sqrt{(k - m\omega^2)^2 + (c\omega)^2}}, \hfill (80)$$

the same as equation (75) but derived using $e^{i\omega t}$ in just three simple lines.

Equation (79) may be written in terms of the dynamic variables, $\omega_n$ and $\zeta$. Dividing the numerator and the denominator of equation (75) by $k$, and
noting that $F/k$ is a static displacement, $x_{st}$, we obtain

$$\frac{X(\omega)}{F(\omega)} = \frac{1/k}{(1 - \frac{m}{k}\omega^2) + i \left(\frac{c}{k}\omega\right)}, \quad (81)$$

$$X(\omega) = \frac{F(\omega)/k}{\left(1 - \left(\frac{\omega}{\omega_n}\right)^2\right) + i \left(2\zeta\frac{\omega}{\omega_n}\right)}, \quad (82)$$

$$\frac{X(\Omega)}{x_{st}} = \frac{1}{(1 - \Omega^2) + i \left(2\zeta\Omega\right)}, \quad (83)$$

$$\frac{\bar{X}(\Omega)}{x_{st}} = \frac{1}{\sqrt{(1 - \Omega^2)^2 + (2\zeta\Omega)^2}}, \quad (84)$$

where the frequency ratio $\Omega$ is the ratio of the forcing frequency to the natural frequency, $\Omega = \omega/\omega_n$. This equation is called the dynamic amplification factor. It is the factor by which a static displacement response is amplified due to the fact that the external forcing is dynamic. See Figure 8.
Figure 8. The dynamic amplification factor for direct external forcing, \( \bar{X}/x_{\text{st}} \), equation (83).

To summarize, the steady state response of a simple oscillator directly excited by a harmonic force, \( f(t) = \bar{F}\cos\omega t \), may be expressed in the form of equation (7)

\[
x(t) = \frac{\bar{F}/k}{\sqrt{(1 - \Omega^2)^2 + (2\zeta\Omega)^2}} \cos(\omega t + \theta), \quad \tan \theta = \frac{-2\zeta\Omega}{1 - \Omega^2}
\]  

(85)

or, equivalently, in the form of equation (8)

\[
x(t) = \frac{\bar{F}/k}{(1 - \Omega^2)^2 + (2\zeta\Omega)^2} \left[ (1 - \Omega^2) \cos \omega t + (2\zeta\Omega) \sin \omega t \right],
\]

(86)

where \( \Omega = \omega/\omega_n \).
3.2 Inertial Forcing

When the dynamic loads are caused by motion of the supports (or the ground, as in an earthquake) the forcing on the oscillator is the inertial force resisting the ground acceleration, which equals the mass of the oscillator times the ground acceleration, \( f(t) = -m\ddot{z}(t) \).

![Diagram of an oscillator](image)

Figure 9. The proto-typical simple oscillator subjected to base motions, \( z(t) \)

\[
m ( \ddot{x}(t) + \dddot{z}(t) ) + c\dot{x}(t) + kx(t) = 0 \quad (87)
\]

\[
m\ddot{x}(t) + c\dot{x}(t) + kx(t) = -m\dddot{z}(t) \quad (88)
\]

\[
\dddot{x}(t) + 2\zeta\omega_n\ddot{x}(t) + \omega_n^2x(t) = -\dddot{z}(t) \quad (89)
\]

Note that equation (89) is independent of mass. Systems of different masses but with the same natural frequency and damping ratio have the same behavior and respond in exactly the same way to the same support motion.

If the ground displacements are sinusoidal \( z(t) = \tilde{Z}\cos\omega t \), then the ground accelerations are \( \dddot{z}(t) = -\tilde{Z}\omega^2\cos\omega t \), and \( f(t) = m\tilde{Z}\omega^2\cos\omega t \). Using the complex exponential formulation, we can find the steady state response as a function of the frequency of the ground motion, \( \omega \).

\[
m\ddot{x}(t) + c\dot{x}(t) + kx(t) = m\tilde{Z}\omega^2\cos\omega t = mZ(\omega)\omega^2e^{i\omega t} + mZ^*(\omega)\omega^2e^{-i\omega t} \quad (90)
\]

The steady-state response can be expressed as the sum of independent complex exponentials, \( x(t) = X(\omega)e^{i\omega t} + X^*(\omega)e^{-i\omega t} \). The positive exponent parts are independent of the negative exponent parts and can be analyzed separately.
Assuming persistent excitation and ignoring the transient response (the particular part of the solution), the response will be harmonic. Considering the “positive exponent” part of the forcing \( mZ(\omega)\omega^2 e^{i\omega t} \), the “positive exponent” part of the steady-state response will have a form \( X e^{i\omega t} \). Substituting these expressions into the differential equation (90), collecting terms, and factoring out the exponential \( e^{i\omega t} \), the frequency response function is

\[
\frac{X(\omega)}{Z(\omega)} = \frac{m\omega^2}{(k - m\omega^2) + i(c\omega)},
\]

where \( \Omega = \omega/\omega_n \) (the forcing frequency over the natural frequency), and

\[
\left| \frac{X(\Omega)}{Z(\Omega)} \right| = \frac{\Omega^2}{\sqrt{(1 - \Omega^2)^2 + (2\zeta \Omega)^2}} \tag{92}
\]

See Figure 10.

Finally, let’s consider the motion of the mass with respect to a fixed point. This is called the total motion and is the sum of the base motion plus the motion relative to the base, \( z(t) + x(t) \).

\[
\frac{X + Z}{Z} = \frac{X}{Z} + 1 = \frac{\Omega^2 + (1 - \Omega^2) + i(2\zeta \Omega)}{(1 - \Omega^2) + i(2\zeta \Omega)} = \frac{1 + i(2\zeta \Omega)}{1 - \Omega^2 + i(2\zeta \Omega)} \tag{93}
\]

and

\[
\left| \frac{X + Z}{Z} \right| = \frac{\sqrt{1 + (2\zeta \Omega)^2}}{\sqrt{(1 - \Omega^2)^2 + (2\zeta \Omega)^2}} = \text{Tr}(\Omega, \zeta). \tag{94}
\]

This function is called the transmissibility ratio, \( \text{Tr}(\Omega, \zeta) \). It represents the ratio of the total response amplitude \( X + Z \) to the base motion amplitude \( Z \), whether (both) \( X \) and \( Z \) correspond to position, velocity, or acceleration. See figure 11.

For systems that have a longer natural period (lower natural frequency) than the period (frequency) of the support motion, (i.e., \( \Omega > \sqrt{2} \)), the transmissibility ratio is less than “1” especially for low values of damping \( \zeta \). In such systems the motion of the mass is less than the motion of the supports and we say that the mass is isolated from motion of the supports.
Figure 10. The dynamic amplification factor for inertial loading, $\bar{X}/\bar{Z}$, equation (91).

Figure 11. The transmissibility ratio $|\frac{(X+Z)}{Z}| = \text{Tr}(\Omega, \zeta)$, equation (93).
3.3 Eccentric-Mass Forcing

Another type of sinusoidal forcing which is important to machine vibration arises from the rotation of an eccentric mass. Consider the system shown in Figure 12 in which a mass $\mu m$ is attached to the primary mass $m$ via a rigid link of length $r$ and rotates at an angular velocity $\omega$. In this single degree of freedom analysis, the motion of the primary mass is constrained to lie along the $x$ coordinate and the forcing of interest is the $x$-component of the reactive centrifugal force. This component is $\mu m r \omega^2 \cos(\omega t)$ where the angle $\omega t$ is the counter-clockwise angle from the $x$ coordinate. The equation of motion with this forcing is

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = \mu m r \omega^2 \cos(\omega t) \quad (95)$$

This expression is simply analogous to equation (77) in which $\bar{F} = \mu m r \omega^2$. With a few substitutions, the frequency response function is found to be

$$\frac{X}{\mu r} = \frac{\Omega^2}{(1 - \Omega^2) + i (2\zeta \Omega)}, \quad (96)$$

which is completely analogous to equation (91). The plot of the frequency response function of equation (96) is simply proportional to the function plotted in Figure 10. The magnitude of the dynamic force transmitted between a machine supported on dampened springs and the base, $|f_T|$, is the sum of the forces in the springs and the dampers. The ratio of the transmitted force to the force generated by the eccentric mass, $\mu m r \omega^2$, is the transmissibility.
ratio, (94).

$$\frac{|f_T|}{\mu m r \omega^2} = \text{Tr}(\Omega, \zeta)$$

(97)

Note, here, though, that the denominator, $\mu m r \omega^2$, increases with $\omega^2$. The transmitted force amplitude increases with $\mu \omega^2 \text{Tr}(\Omega, \zeta)$. Multiplying both sides of equation (97) by $\Omega^2$ we obtain the transmission ratio.

$$\frac{|f_T|}{\mu m r \omega_n^2} = \Omega^2 \text{Tr}(\Omega, \zeta)$$

(98)

Unlike the transmissibility ratio, which asymptotically approaches “0” with increasing $\Omega$, the vibratory force transmitted from an eccentric mass excitation is “0” when $\Omega = 0$ but increases with $\Omega$ for $\Omega > \sqrt{2}$. This increasing effect is significant for $\zeta > 0.2$, as shown in Figure 13. For high frequency

![Figure 13. The transmission ratio $\Omega^2 \text{Tr}(\Omega, \zeta)$, equation (98).](image-url)
ratios ($\omega_n < \omega/2$) and low damping ratios ($\zeta < 0.2$), the force transmitted from the rotating machinery to the floor ($|f_T|$) is less than half of the force generated by the machinery ($\mu mr\omega^2$). Further, for $\zeta \approx 0.2$, the value of the transmitted force is roughly independent of the forcing frequency.

3.4 Finding the damping from the peak or bandwidth of the frequency response function

For lightly damped systems, the frequency ratio of the resonant peak, the amplification of the resonant peak, and the width of the resonant peak are functions of the damping ratio only. Consider two frequency ratios $\Omega_1$ and $\Omega_2$ such that $|H(\Omega_1, \zeta)|^2 = |H(\Omega_2, \zeta)|^2 = |H|_{\text{peak}}^2/2$ where $|H(\Omega, \zeta)|$ is one of the frequency response functions described in earlier sections. The frequency ratio corresponding to the peak of these functions $\Omega_{\text{peak}}$, the value of the peak of these functions, $|H|_{\text{peak}}^2$, and $\Omega_2^2 - \Omega_1^2$ are given in Table 1. Note that the peak coordinate depends only upon the damping ratio, $\zeta$.

Since $\Omega_2^2 - \Omega_1^2 = (\Omega_2 - \Omega_1)(\Omega_2 + \Omega_1)$ and since $\Omega_2 + \Omega_1 \approx 2$,

$$\zeta \approx \frac{\Omega_2 - \Omega_1}{2} \quad (99)$$

which is called the “half-power bandwidth” approximation for the damping ratio. For the first, second, and fourth frequency response functions listed in Table 1 the approximation is accurate to within 5% for $\zeta < 0.20$ and is accurate to within 1% for $\zeta < 0.10$.

Table 1. Peak coordinates for various frequency response functions.

| $H(\Omega, \zeta)$ | $\Omega_{\text{peak}}$ | $|H|_{\text{peak}}^2$ | $\Omega_2^2 - \Omega_1^2$ |
|-------------------|-----------------|-----------------|-------------------|
| $\frac{1}{(1-\Omega^2)+i(2\zeta\Omega)}$ | $\sqrt{1-2\zeta^2}$ | $\frac{1}{4\zeta^2(1-\zeta^2)}$ | $4\zeta\sqrt{1-\zeta^2}$ |
| $\frac{i\Omega}{(1-\Omega^2)+i(2\zeta\Omega)}$ | $1$ | $\frac{1}{4\zeta^2}$ | $4\zeta\sqrt{1+\zeta^2}$ |
| $\frac{\Omega^2}{(1-\Omega^2)+i(2\zeta\Omega)}$ | $\frac{1}{\sqrt{1-2\zeta^2}}$ | $\frac{1}{4\zeta^2(1-\zeta^2)}$ | $\frac{4\zeta\sqrt{1-\zeta^2}}{1-8\zeta^2(1-\zeta^2)}$ |
| $\frac{1+i(2\zeta\Omega)}{(1-\Omega^2)+i(2\zeta\Omega)}$ | $\frac{((1+8\zeta^2)^{1/2}-1)^{1/2}}{2\zeta}$ | $\frac{8\zeta^4}{8\zeta^4-4\zeta^2-1+\sqrt{1+8\zeta^2}}$ | ouch. |
3.5 Summary of harmonically forced response of simple oscillators

To review, some of the important expressions relating to the harmonically forced response of a simple oscillator describe:

- harmonic response with amplitude $\bar{X}$ and phase shift $\theta$ at the forcing frequency $\omega$
  \[ x(t) = \bar{X} \cos(\omega t + \theta) \]
- the frequency ratio (forcing frequency / natural frequency)
  \[ \Omega = \frac{\omega}{\omega_n} \]
- equations of motion of a simple oscillator with direct harmonic forcing
  \[ \ddot{x}(t) + 2\zeta\omega_n\dot{x}(t) + \omega_n^2 x(t) = \frac{1}{m}\bar{F} \cos \omega t \]
- static displacement
  \[ x_{st} = \frac{\bar{F}}{k} \]
- frequency response of simple oscillator with direct harmonic forcing, Figure 8.
  \[ \frac{\bar{X}(\Omega)}{x_{st}} = \frac{1}{\sqrt{(1 - \Omega^2)^2 + (2\zeta\Omega)^2}} \]
- equations of motion of a simple oscillator with support excitation
  \[ \ddot{x}(t) + 2\zeta\omega_n\dot{x}(t) + \omega_n^2 x(t) = \bar{Z}\omega^2 \cos \omega t \]
- frequency response of the relative response of a simple oscillator to harmonic base motion, Figure 10.
  \[ \frac{|X(\Omega)|}{|Z(\Omega)|} = \frac{\Omega^2}{\sqrt{(1 - \Omega^2)^2 + (2\zeta\Omega)^2}} \]
- frequency response of the total response of a simple oscillator to harmonic base motion, Figure 11.
  \[ \frac{|X + Z|}{Z} = \frac{\sqrt{1 + (2\zeta\Omega)^2}}{\sqrt{(1 - \Omega^2)^2 + (2\zeta\Omega)^2}} \]
4 Real and Imaginary. Even and Odd. Magnitude and Phase.

Using the rules of complex division, it is not hard to show that

\[
\begin{align*}
\text{Re}[H(\Omega, \zeta)] &= \text{Re}[H(-\Omega, \zeta)] \\
\text{Im}[H(\Omega, \zeta)] &= -\text{Im}[H(-\Omega, \zeta)].
\end{align*}
\tag{100-101}
\]

That is, \( \text{Re}[H(\Omega)] \) is an even function and \( \text{Im}[H(\Omega)] \) is an odd function. This fact is true for any dynamical system for which the inputs and outputs are real-valued.

For any frequency response function, the magnitude \( |H(\Omega, \zeta)| \) and phase \( \theta(\Omega, \zeta) \) may be found from

\[
\begin{align*}
|H(\Omega, \zeta)|^2 &= (\text{Re}[H(\Omega, \zeta)])^2 + (\text{Im}[H(\Omega, \zeta)])^2 \\
\tan \theta(\Omega, \zeta) &= \frac{\text{Im}[H(\Omega, \zeta)]}{\text{Re}[H(\Omega, \zeta)]}.
\end{align*}
\tag{102-103}
\]

Expressions for the magnitude of various frequency response functions are given by equations (83), (92), and (93). The magnitude and phase lag of these functions are plotted in Figures 8, 10, and 11. Real and imaginary parts of \( H(\Omega, \zeta) \) are plotted in Figure 14. Note the following:

- The real and imaginary parts are even and odd, respectively.
- The real part of \( X/x_{st} \) (force to response displacement) is zero at \( \Omega = 1 \). The phase at \( \Omega = 1 \) is 90 degrees.
- The real part of \( X/Z \) (support motion to response motion) is zero at \( \Omega = 1 \). The phase at \( \Omega = 1 \) is 90 degrees.
- The imaginary part of \( i\Omega X/x_{st} \) (force to response velocity) is zero at \( \Omega = 1 \). The phase at \( \Omega = 1 \) is 90 degrees.
- The real part of \( i\Omega X/x_{st} \) (force to response velocity) is maximum at \( \Omega = 1 \).
- The real part of \( i\Omega X/x_{st} \) (force to response velocity) is positive for all values of \( \Omega \).
Figure 14. The real (even) and imaginary (odd) parts of frequency response functions, $\zeta = 0.1$. 
5 Combined free and sinusoidally-forced response

The analyses of the previous sections describe (a) the transient (homogeneous) response of a simple oscillator to initial conditions \( x(0) = d_o \) and \( \dot{x}(0) = v_o \), and (b) the steady-state harmonic (particular) response of a simple oscillator to sinusoidal forcing \( f(t) = \bar{F} \cos \omega t \). The harmonic steady state response does not consider the transient from initial conditions.

The combined transient and harmonic response is the sum of the homogeneous solution, (??) or (40) (depending on the value of \( \zeta \)) and the particular solution, (86). The coefficients \( a \) and \( b \) are found by matching the combined response to the initial conditions \( x(0) = d_o \) and \( \dot{x}(0) = v_o \). So doing, for a sinusoidal forcing \( f(t) = \bar{F} \cos \omega t \), \( \omega_n > 0 \), \( \zeta < 1 \), and \( \zeta \neq 0 \),

\[
x(t) = e^{-\zeta \omega_n t} (a \cos \omega_d t + b \sin \omega_d t) \]
\[
+ \frac{\bar{F}/k}{(1 - \Omega^2)^2 + (2\zeta \Omega)^2} \left[ (1 - \Omega^2) \cos \omega t + (2\zeta \Omega) \sin \omega t \right],
\]

(104)
solving \( x(0) = d_o \) for \( a \) gives

\[
a = d_o - \frac{\bar{F}/k}{(1 - \Omega^2)^2 + (2\zeta \Omega)^2} (1 - \Omega^2)
\]

(105)

Deriving \( \dot{x}(t) \) and solving \( \dot{x}(0) = v_o \) for \( b \) gives

\[
b = \frac{1}{\omega_d} \left( v_o + \zeta \omega_n a - \frac{\bar{F}/k}{(1 - \Omega^2)^2 + (2\zeta \Omega)^2} \omega(2\zeta \Omega) \right)
\]

(106)

Figures 15 and 16 give two examples of combined response. Note that even when initial displacements and velocities are zero, the transient portion of the response can be much larger than the steady-state portion of the response.
Figure 15. Combined free and forced response of a simple oscillator, $\omega_n = \pi$ rad/s, $\zeta = 0.05$, $d_o = 5$ m, $v_o = 10$ m/s, $\omega = 2\pi$ rad/s, $F = 80$ N, $m = 1$ kg

Figure 16. Combined free and forced response of a simple oscillator, $\omega_n = \pi$ rad/s, $\zeta = 0.05$, $d_o = 0$, $v_o = 0$, $\omega = 2\pi$ rad/s, $F = -3.9$ N, $m = 1$ kg

Figure 17. Combined free and forced response of a simple oscillator, in resonance $\omega_n = \pi$ rad/s, $\zeta = 0.05$, $d_o = 0$, $v_o = 0$, $\omega = \omega_n$, $F = 1$ N, $m = 1$ kg
6 Undamped Resonance

The combination of free and forced responses is a weighted sum of four linearly independent terms \( \cos \omega_d t \), \( \sin \omega_d t \), \( \cos \omega t \), and \( \sin \omega t \), from which any set of two initial conditions \((d_o \text{ and } v_o)\), and magnitude, and phase may be specified. If the forcing is applied at the natural frequency and the damping is zero, then \( \omega_d = \omega_n = \omega \), and there are only two linearly independent terms. So solutions of the form of equation (104) can not satisfy the differential equation for undamped resonance

\[
\ddot{x}(t) + \omega_n^2 x(t) = \frac{F}{m} \cos \omega_n t
\]

(107)

As seen in the case of damped resonance, Figure 18, the response is enveloped by

\[
-\frac{F}{k} \frac{1-e^{-\omega_n \zeta t}}{2\zeta} \leq x(t) \leq +\frac{F}{k} \frac{1-e^{-\omega_n \zeta t}}{2\zeta}
\]

(108)

Without damping, however, we may expect the resonant response to grow without bound. A trial solution in this case could be

\[
x(t) = a \ t \cos \omega_n t + b \ t \sin \omega_n t
\]

(109)

The solution

\[
x(t) = \frac{F}{2k} \ t \ \sin \omega_n t
\]

(110)

satisfies equation (107) and initial conditions at rest \( d_o = 0, \ v_o = 0 \).

Figure 18. Undamped resonance of a simple oscillator \( \omega_n = \pi \ \text{rad/s}, \ \zeta = 0, \ d_o = 0, \ v_o = 0, \ \omega = \omega_n, \ F = 1 \ \text{N}, \ m = 1 \ \text{kg} \)
8 Vibration Sensors

A vibration sensor may be accurately modeled as an inertial mass supported by elements with stiffness and damping (i.e. as a single degree of freedom oscillator). Vibration sensors mounted to a surface ideally measure the velocity or acceleration of the surface with respect to an inertial reference frame. The electrical signals generated by vibration sensors are actually proportional to the velocity of the mass with respect to the sensor’s case (for seismometers) or the deformation of the elastic elements of the sensor (for accelerometers). The frequency response functions and sensitivities of seismometers and accelerometers have qualitative differences.

8.1 Seismometers

Seismometers transduce the velocity of a magnetic inertial mass to electrical current in a coil. The transduction element of seismometers is therefore based on Ampere’s Law, and seismometers are made from sprung magnetic masses that are guided to move within a coil fixed to the instrument housing. The electrical current generated within the coil is proportional to the velocity of the magnetic mass relative to the coil; so the mechanical input is the velocity of the case \( \dot{z}(t) = i\omega Z e^{i\omega t} \) and the electrical output is proportional to the velocity of the inertial mass with respect to the case \( v(t) = \kappa \dot{z}(t) = \kappa i\omega X(\omega)e^{i\omega t} \). These variables are related in the frequency domain by equation (91).

\[
\frac{V}{i\omega Z} = \frac{\kappa i\omega X}{i\omega Z} = \frac{\kappa X}{Z} = \frac{\kappa \Omega^2}{(1 - \Omega^2) + i(2\zeta\Omega)} \tag{111}
\]

The sensitivity of seismometers approaches zero as \( \Omega \) approaches zero. In order for seismometers to be sensitive to very low amplitude motion, the natural frequency of seismometers is designed to be quite small (less than 0.5 Hz, and sometimes less than 0.1 Hz).

In comparison to accelerometers, seismometers are heavy, large, delicate, sensitive, high output sensors which do not require external power or amplification. Converting seismometer voltage to velocity or acceleration involves
a dynamic model for the sensor, typically represented as frequency domain poles and zeros.

8.2 Accelerometers

Accelerometers are themselves simple oscillators, with an input \( f(t) = -m\ddot{z}(t) \), and a voltage output proportional to the relative displacement, \( v(t) = \kappa x(t) \), where \( \kappa \) is related to the accelerometer sensitivity (in volts/m/s\(^2\)). Accelerometers transduce the deformation of inertially-loaded elastic elements within the sensor to an electrical charge, a voltage, or a current. Accelerometers may be designed with many types of transduction elements, including piezo-electric materials, strain-gages, variable capacitance components, and feed-back stabilization.

In all cases, the mechanical input to the accelerometer is the acceleration of the case \( \ddot{z}(t) = -\omega^2 Z e^{i\omega t} \), the electrical output is proportional to the deformation of the spring \( v(t) = \kappa x(t) = \kappa X e^{i\omega t} \), and these variables are related in the frequency domain by

\[
\frac{V}{-\omega^2 Z} = \frac{-\kappa/\omega_n^2}{(1 - \Omega^2) + i(2\zeta \Omega)}
\]

So the sensitivity of an accelerometer increases with decreasing natural frequency.

Piezo-electric accelerometers have natural frequencies in the range of 1 kHz to 20 kHz and damping ratios in the range of 0.5% to 1.0%. Because of electrical coupling considerations and the sensitivity of peizo-electric accelerometers to low-frequency temperature transients, the sensitivity and signal-to-noise ratio of piezo-electric accelerometers below 1 Hz can be quite poor.

Micro-machined electro-mechanical silicon (MEMS) accelerometers are monolithic with their signal-conditioning micro-circuitry. They typically have natural frequencies in the 100 Hz to 500 Hz range and are accurate down to frequencies of 0 Hz (constant acceleration, e.g., gravity). These sensors are damped to a level of about 70% of critical damping.
Force-balance accelerometers utilize feedback circuitry to magnetically stabilize an inertial mass. The force required to stabilize the mass is directly proportional to the acceleration of the sensor. Such sensors can be made to measure accelerations in the $\mu g$ range down to frequencies of 0 Hz, and have natural frequencies on the order of 100 Hz, also with damping of about 70% of critical damping.

Accelerometers are typically light, small, and rugged but require electrical power, amplification, and signal conditioning.

Given the sensor sensitivity, natural frequency and damping ratio, the accelerometer’s sensor dynamics can be corrected by numerically differentiating $x(t) = v(t)/\kappa$ once to obtain $\dot{x}(t)$, and again to obtain $\ddot{x}(t)$. Then, the “instrument-corrected” (true) acceleration at each point in time can be obtained from

$$\ddot{z}(t) = -\left(\ddot{x}(t) + 2\zeta \omega_n \dot{x}(t) + \omega_n^2 x(t)\right)$$  \hspace{1cm} (113)

For sensors with a low natural frequency, this kind of instrument correction is essential. For instruments with natural frequencies greater than about ten times the frequency range of the measured signals, instrument correction is not significantly important. Further, if the signal to noise ratio is less than about 10:1, instrument correction has no discernible effect.

8.3 Design Considerations for Accelerometers

Accelerometers should have a uniform amplitude spectrum and a linear phase spectrum (minimum phase distortion) over the frequency bandwidth of the application. The phase distortion is the deviation in the phase lag from a linear phase shift. Figure 19 is a close-up of the frequency-response function of equation (112) over the typical frequency band width of accelerometer applications.

A linear phase spectrum is equivalent to a constant time delay. Consider a phase-lagged dynamic response in which the phase $\theta$ changes linearly with frequency, $\theta = \tau \omega$.

$$v(t) = |V| \cos(\omega t + \tau \omega)$$

$$= |V| \cos(\omega(t + \tau))$$  \hspace{1cm} (114)
shifted which is the same as a response that is shifted in time by a constant time increment of $\tau$ for all frequencies. As can be seen in Figure 19, a level of damping in the range of 0.67 to 0.71 provides an amplitude distortion of less than 0.5% and a phase distortion of less than 0.5 degrees for a bandwidth up to 30% of the sensor natural frequency. A sensor damping of $\zeta = \sqrt{2}/2$ provides an optimally flat amplitude response and an extremely small phase distortion ($< 0.2$ degrees?) up to 25% of the sensor natural frequency. For frequency ratios in this range, the phase spectrum is

$$\theta(\Omega) = \tan^{-1} \left[ \frac{-2\zeta\Omega}{1 - \Omega^2} \right] \approx -2\zeta\Omega$$

(115)

giving a time lag $\tau$ of approximately $2\zeta/\omega_n$. For $\zeta = \sqrt{2}/2$, the time lag $\tau$ evaluates to $\tau = \sqrt{2}/\omega_n = \sqrt{2}/(2\pi f_n) \approx 0.23 T_n$.

9 Simulation for exploration

The behavior of simple oscillators may be explored by studying animated simulations of inertially-forced systems with different frequency ratios and damping ratios. Both transient and steady-state dynamics are involved in these solutions. The steady-state portion of the time-domain solutions can be compared to frequency-domain solutions (for steady-state response). And animation of the time domain solution visually demonstrates the magnitude and phase relationships described by frequency-domain solutions. Animation facilitates the interpretation of magnitude and phase relationships in the context of observations in the time-domain.

Figures 10 and 11 illustrate the behavior in the frequency-domain. Figure 10, labeled frequency response: \( Z \) to \( X \), illustrates the dynamic amplification of the oscillator’s steady-state displacement response, \( x(t) = \bar{X} \cos(\omega t + \theta) \), subjected to sinusoidal ground displacements, \( z(t) = \bar{Z} \cos \omega t \). At a frequency ratio (\( \Omega = \omega/\omega_n \)) of one, (the forcing frequency, \( \omega \), equals the resonant frequency, \( \omega_n = \sqrt{k/m} \)) the response motion can be many times greater than the support motion (\( |X/Z| \gg 1 \)). As the damping (\( \zeta \)) increases, the amount of amplification decreases throughout the frequency range. The displacement amplification at resonance (\( \Omega = 1 \)) is equal to \( 1/(2\zeta) \). For example, if the damping ratio, \( \zeta \), equals five percent (0.05), the amplification at resonance is 10. Also note that at resonance, the displacement response lags the base displacement by ninety degrees for all values of damping. If the frequency of the ground displacement is practically zero (the ground simply has a nearly constant static displacement) \( (z(t) \approx \text{const.} \text{ and } \ddot{z}(t) \approx 0) \) and the relative displacement of the oscillator with respect to its support point is zero (\( |X/Z| = 0 \)). If the frequency of the ground displacement is high (\( \Omega > 2 \)) the oscillator remains relatively stationary while its support point moves. In this case the structural deformation is equal and opposite to the ground displacement. The dynamic amplification factor, \( |X/Z| \), is close to 1, and the displacement response lags the ground displacement by 180 degrees.

Figure 11, labeled transmissibility: \( Z \) to \( (X+Z) \), illustrates the relation-
ship between the support point displacement, \( Z \), and the total (or absolute) motion of the oscillator, \( X + Z \), the sum of the support-point motion and the relative motion of the oscillator with respect to its support. This relationship is used to analyze the isolation of an oscillator from vibrations of its supports. The goal in vibration isolation is to minimize or reduce the total response \((x + z)\), not the relative response, \( x \); that is, to design for a natural frequency and damping ratio that has very low transmissibility at the frequency (or frequencies) of the support motion. For forcing frequencies near the natural frequency (near resonance), adding damping reduces the dynamic amplification. At a frequency ratio \( \Omega \) of \( \sqrt{2} \), the total response amplitude is equal to the base motion amplitude, regardless of the damping ratio. At higher frequencies \((\Omega > \sqrt{2})\), increasing damping increases the dynamic amplification. The phase relationship for transmissibility is more complicated than the phase relationship for the frequency response function from \( Z \) to \( X \). The phase lags at all frequencies, including resonance \((\Omega = 1)\), depend on the value of damping.

Animations of computer simulations can help in developing a fuller understanding of inertially-forced vibrations. To use this code, start by downloading \texttt{simple_oscillator_sim.m} and \texttt{simple_oscillator_anim.m}. The program \texttt{simple_oscillator_sim.m} simulates the response of a linear oscillator to sinusoidal input, \( z(t) = \bar{Z} \cos(2\pi f_g t) \). To use it:

1. Start Matlab and navigate to your new \texttt{cee541/m-files} folder.
2. Type \texttt{>> help simple_oscillator_sim} for information on how to run the program.
3. Run the program with a command like \texttt{>> simple_oscillator_sim(5,1,0.1)} to simulate and animate the response to a 5 Hz forcing frequency of an oscillator with a natural frequency of 1 Hz and a damping ratio of 0.10. Separate the four plots on your monitor so that you can observe the animation in all four figures as you run simulations.

Using information provided in Figures 10 and 11 predict the amplifi-
tudes and phases of $X/Z$ and $(X + Z)/Z$ for a value of the *ground motion frequency* of 1.0 cycles/second, a value of the natural frequency of 1.0 cycles/second, and a damping ratio of 0.10, Then run the simulation using

```matlab
>> simple_oscillator_sim(1,1,0.1)
```

Observe the dynamic amplification and phase of the response, and confirm your prediction. Next set the ground motion frequency to 3. Before running the simulation use Figures 10 and 11 to predict the amplitudes and phases of $X/Z$ and $(X + Z)/Z$. Confirm your prediction by running a simulation.  

```matlab
>> simple_oscillator_sim(1,0.3,0.1)
```

Notice that the oscillator remains relatively stationary while the ground moves beneath it. The total acceleration of the mass is smaller than the acceleration of the base. The relative displacement of the mass with respect to the base is nearly equal and opposite to the displacement of the base. This is considered good isolation performance. The total acceleration response is much less than the ground acceleration, and the relative displacement response is equal and opposite to the ground displacement.

Now, increase the damping ratio from 10 percent to 50 percent, use Figures 10 and 11 to make a new prediction and repeat the simulation. Notice that the total acceleration response is *larger* than when the damping was 10 percent. Note also that the total acceleration response is more ‘in phase’ with the ground acceleration. Finally increase the damping to 99 percent (0.99). Notice that the amplitude and duration of the initial transient is much shorter. Finally, notice how the total accelerations increase further as the higher damping level couples the mass more tightly to the ground.

Figure 3 in the Matlab simulation displays a Lissajous figure of force vs deformation. This is a plot of the force in the spring and damper ($kx(t) + cx(t)$) vs the deformation of the spring, $x(t)$. Note that if the damping ratio is low, the restoring force is basically just $kx(t)$ and the hysteresis plot simply shows the force vs displacement relationship for the spring (a straight line).

As the damping increases, the restoring force hysteresis plot becomes more like an ellipse, and as the damping ratio gets very large the force approaches $cx(t)$. The area of the ellipse has units of force $\times$ displacement and
is equal to the energy dissipated per cycle in the damper. The bigger the loops, the more energy is dissipated into heat, and the less energy goes into shaking the oscillator.

Explore the effect of other values of the ground motion frequency and the damping ratio and notice the relationship between the frequency response \( X/Z \) vs. \( \Omega \), transmissibility \( (X+Z)/Z \) vs. \( \Omega \) (Figures 10 and 11), the animation, the time history plots, and restoring force hysteresis plots \( kx+c\dot{x} \) vs. \( x \). Note how the amplitude ratio and the phase of the frequency response and the transmissibility are affected by the ground motion frequency and the damping ratio.

Investigate the significance of transients in the response. The relative importance of the transient is linked to the level of damping. Make a figure of the ratio of the peak displacement response to the ground motion displacement amplitude \( \frac{X_{pk\_displ}}{Z_{displ}} \) vs the damping ratio, for \( \Omega \in [0.5, 1.0, 2.0] \), for values of \( \zeta \in [0.02 : 0.02 : 0.5] \). To generate the data for this figure quickly, comment out the plotting function in simple_oscillator_sim.m (around line 66), and write a .m-file that has a nested loop to compute the data, save that data into a matrix, and plot the data.

9.1 Exercises

1. Referring to Figures 10 and 11, for a structure to isolate its contents from base-excited vibration, should its natural frequency be higher, about the same, or lower than the predominate frequencies in the ground excitation? Why? (Note: \( \Omega = \omega / \omega_n = \text{(forcing frequency)} / \text{(natural frequency)} \).)

2. For vibration isolation in linear elastic structural systems, what are the ‘pro’s’ and ‘con’s’ of high damping (\( \zeta > 15\% \))? 

3. For a sinusoidally-base-excited structure with \( \omega_n = (1/3)\omega \), determine the value of \( \zeta \) so that the magnitude of the total response motion \( (X+Z) \) is only fifteen percent of the magnitude of the base motion \( (Z) \). (You’ll need to solve a quadratic equation to do this.)

4. For these values of \( \omega / \omega_n \) and \( \zeta \) what is the ratio of the structural deformation amplitude to the ground motion amplitude \( (X/Z) \)? Since “\((X+Z)/Z = X/Z + 1\)” did you expect the answer for \( X/Z \) to be -0.85? Why do you think it is not -0.85?

5. Include your plot of \( X_{pk\_displ} / Z_{displ} \) vs \( \zeta \) as described on the previous page.
